- Hypothesis Testing
- Interaction Terms

## Polynomial Regression

# Standard Errors

The variances of  $\beta \downarrow 0$  and  $\beta \downarrow 1$  are also called their **standard errors**,  $SE(\beta \downarrow 0), SE(\beta \downarrow 1)$ .

If our data is drawn from a larger set of observations then we can empirically estimate the **standard errors**,  $SE(\beta \downarrow 0), SE(\beta \downarrow 1)$  of  $\beta \downarrow 0$  and  $\beta \downarrow 1$  through bootstrapping.

If we know the variance  $\sigma^2$  of the noise  $\epsilon$ , we can compute  $SE(\beta \downarrow 0), SE(\beta \downarrow 1)$  analytically, using the formulae below:

$$SE(\hat{\beta}_0) = \sigma \sqrt{\frac{1}{n} + \frac{\bar{x}^2}{\sum_i (x_i - \bar{x})^2}}$$

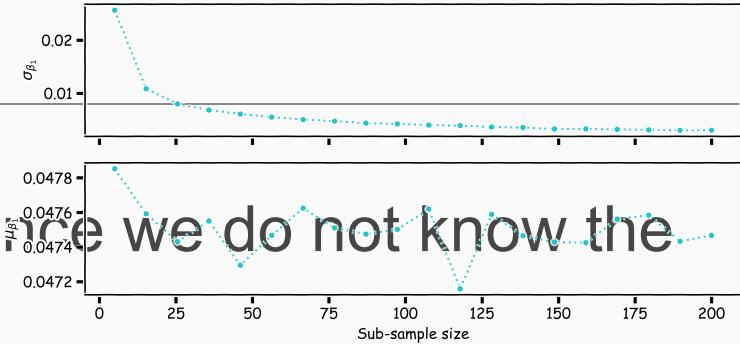

$$SE(\hat{\beta}_1) = \frac{\sigma}{\sqrt{\sum_i (x_i - \bar{x})^2}}$$

# Standard Errors

**More data:**  $n \uparrow$  and  $SE(\hat{\beta}_0) \downarrow \Rightarrow \sigma^2 \downarrow \Rightarrow SE \downarrow$

**Largest coverage:**  $\text{var}(x)$  or  $\sum_i (x_i - \bar{x})^2 \uparrow \Rightarrow SE \downarrow$

**Better data:**  $\sigma^2 \downarrow \Rightarrow SE \downarrow$

$$SE(\hat{\beta}_1) = \sqrt{\frac{1}{\sum_i (x_i - \bar{x})^2}}$$

In practice, we do not know the theoretical value of  $\sigma$  since we do not know the exact distribution of the noise  $\epsilon$ .

Remember:

$$y_{\downarrow i} = f(x_{\downarrow i}) + \epsilon_{\downarrow i} \Rightarrow \epsilon_{\downarrow i} = y_{\downarrow i} - f(x_{\downarrow i})$$

# Standard Errors

In practice, we do not know the theoretical value of  $\sigma$  since we do not know the exact distribution of the noise  $\epsilon$ . However, if we make the following assumptions,

- the errors  $\epsilon \downarrow i = y \downarrow i - \hat{y} \downarrow i$  and  $\epsilon \downarrow j = y \downarrow j - \hat{y} \downarrow j$  are uncorrelated, for  $i \neq j$ ,
- each  $\epsilon \downarrow i$  is normally distributed with mean 0 and variance  $\sigma^2$ ,

then, we can empirically estimate  $\sigma^2$ , from the data and our regression line:

$$\sigma \approx \sqrt{\frac{n \cdot \text{MSE}}{n - 2}} = \sqrt{\frac{\sum_i (y_i - \hat{y}_i)^2}{n - 2}}$$

$$\sigma \approx \sqrt{\sum \frac{(\hat{f}(x) - y_i)^2}{n - 2}}$$

# Standard Errors

---

**More data:**  $n \uparrow$  and  $\sum_i (x_{i\downarrow} - \bar{x})^2 \uparrow \Rightarrow SE \downarrow$

**Largest coverage:**  $var(x)$  or  $\sum_i (x_{i\downarrow} - \bar{x})^2 \uparrow \Rightarrow SE \downarrow$

**Better data:**  $\sigma^2 \downarrow \Rightarrow SE \downarrow$

$$SE(\hat{\beta}_0) = \sigma \sqrt{\frac{1}{n} + \frac{\bar{x}^2}{\sum_i (x_i - \bar{x})^2}}$$
$$SE(\hat{\beta}_1) = \frac{\sigma}{\sqrt{\sum_i (x_i - \bar{x})^2}}$$

**Better model:**  $(f - y_{i\downarrow}) \downarrow \Rightarrow \sigma \downarrow \Rightarrow SE \downarrow$

$$\sigma \approx \sqrt{\sum \frac{(\hat{f}(x) - y_i)^2}{n - 2}}$$

**Question:** What happens to the  $\beta_{0\downarrow}$ ,  $\beta_{1\downarrow}$  under these scenarios?

# Standard Errors

The following results are for the coefficients for TV advertising:

Method	$SE(\beta \downarrow 1)$
Analytic Formula	0.0061
Bootstrap	0.0061

The coefficients for TV advertising but restricting the coverage of x are:

Method	$SE(\beta \downarrow 1)$
Analytic Formula	0.0068
Bootstrap	0.0068

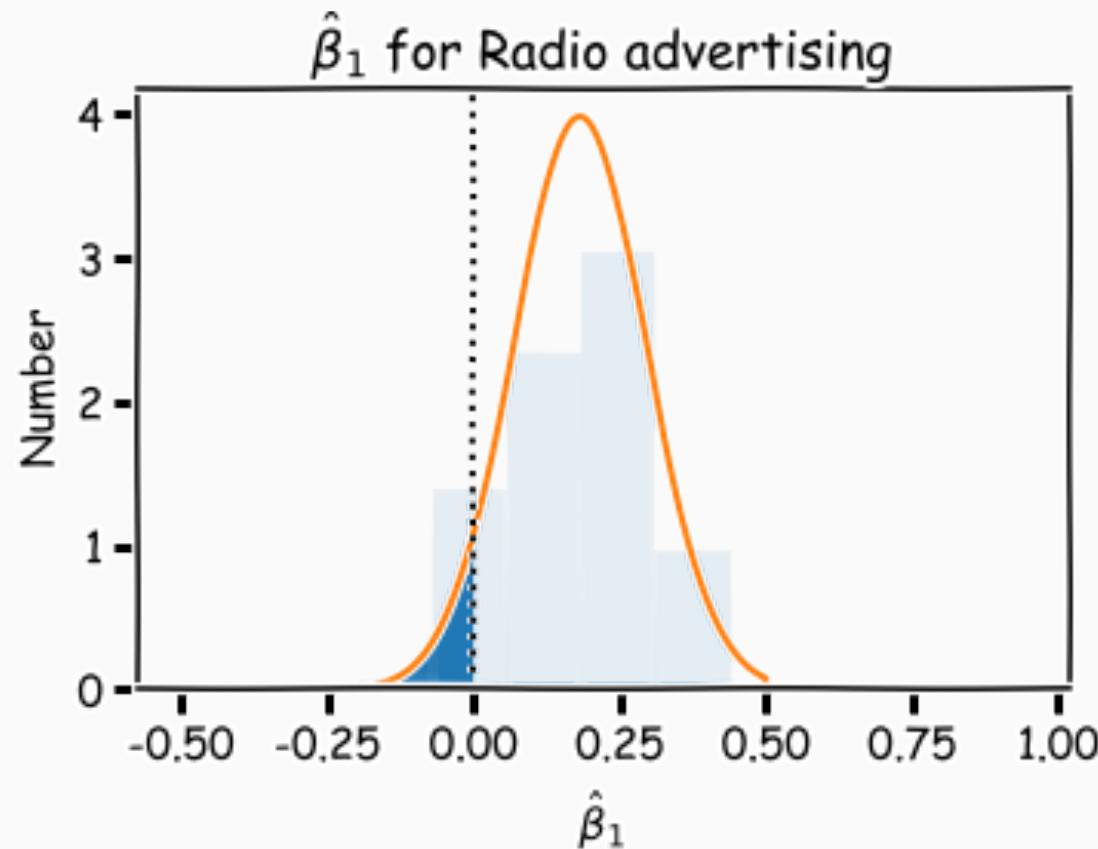

The coefficients for TV advertising but with added **extra** noise:

Method	$SE(\beta \downarrow 1)$
Analytic Formula	0.0028
Bootstrap	0.0023

This makes no sense?

# Importance of predictors

We have discussed finding the importance of predictors, by determining the cumulative distribution from  $\infty$  to 0.

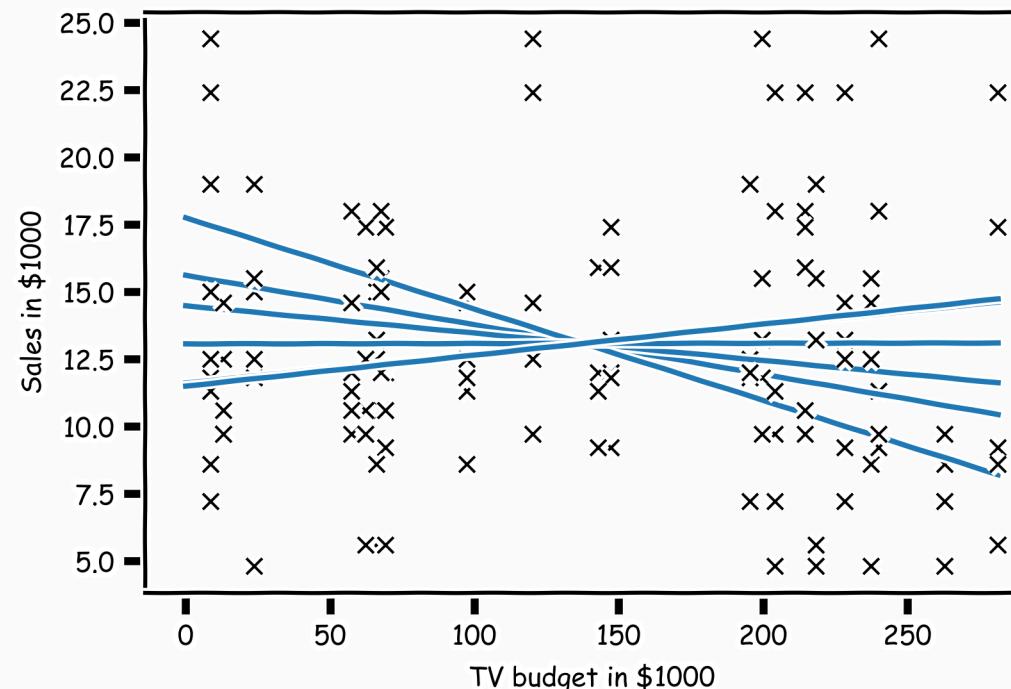

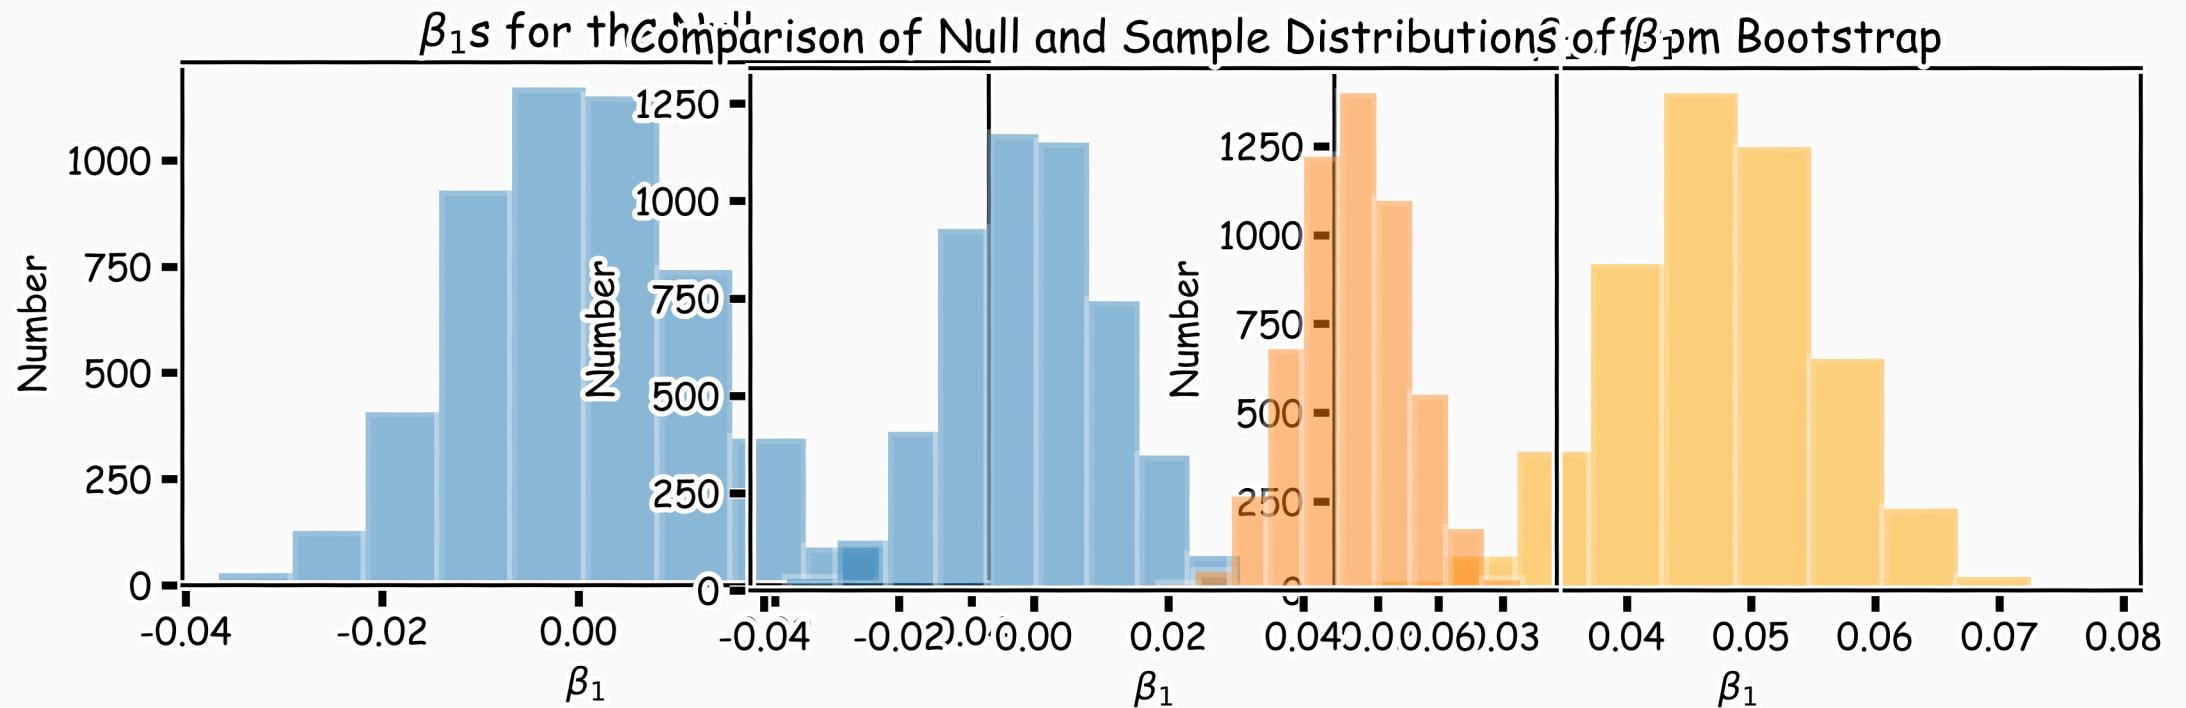

# Hypothesis Testing

Hypothesis testing is a formal process through which we evaluate the validity of a statistical hypothesis by considering evidence **for** or **against** the hypothesis gathered by *random sampling of the data.*

Random sampling of the data  
Shuffle the values of the predictor variable

# Importance of predictors

Translate this to Kevin's language. Let's look at the distance of the estimated value of the coefficient in units of  $SE(\hat{\beta}_1) = \sigma_{\hat{\beta}_1}$ .

$$t = \frac{\hat{\beta}_1 - 0}{SE(\hat{\beta}_1)}$$

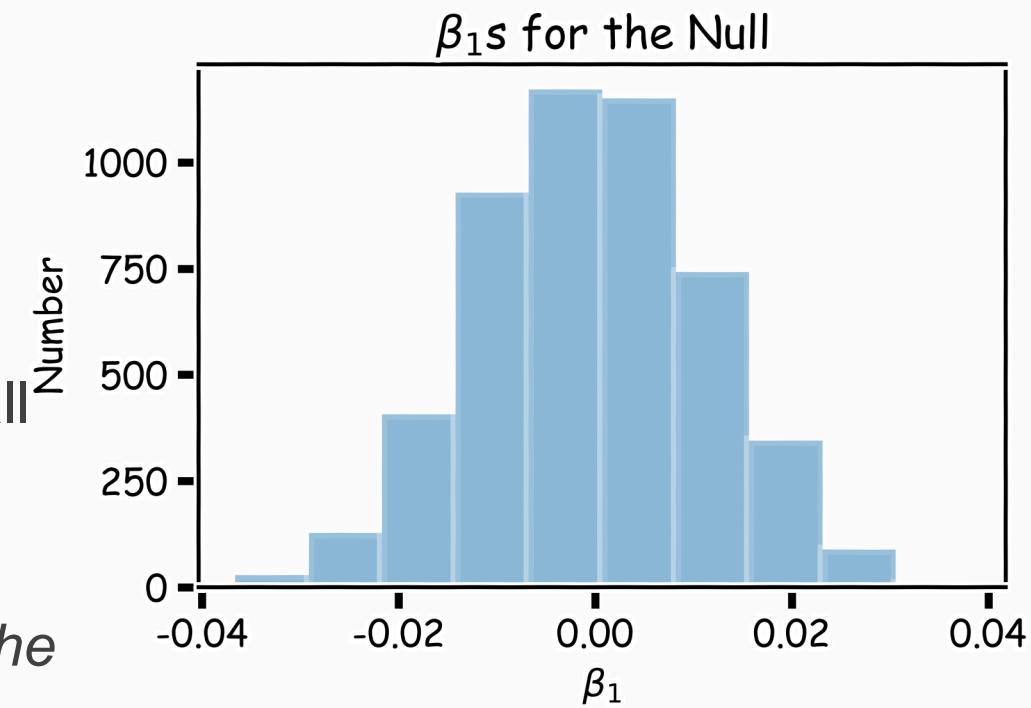

# Importance of predictors

And also evaluate how often a particular value of  $t$  can occur by accident (using the shuffled data)?

We expect that  $t$  will have a *t-distribution with  $n-2$  degrees of freedom*.

To compute the probability of observing any value equal to  $|t|$  or larger, assuming  $\beta_1 = 0$  is easy. We call this probability the **p-value**.

*a small p-value indicates that it is unlikely to observe such a substantial association between the predictor and the response due to chance*

# Hypothesis Testing

Hypothesis testing is a formal process through which we evaluate the validity of a statistical hypothesis by considering evidence for or against the hypothesis gathered by random sampling of the data.

1. State the hypotheses, typically a **null hypothesis**,  $H_0$  and an **alternative hypothesis**,  $H_1$ , that is the negation of the former.
2. Choose a type of analysis, i.e. how to use sample data to evaluate the null hypothesis. Typically this involves choosing a **single test statistic**.
3. **Compute** the test statistic.
4. Use the value of the test statistic to either **reject** or **not reject** the null hypothesis.

# Hypothesis testing

## 1. State Hypothesis:

### Null hypothesis:

$H_{\text{I}0}$  : There is no relation between  $X$  and  $Y$

### The alternative:

$H_{\text{I}\alpha}$  : There is some relation between  $X$  and  $Y$

## 2: Choose test statistics

To test the null hypothesis, we need to determine whether, our estimate for  $\beta_{\text{I}1}$ , is sufficiently far from zero that we can be confident that  $\beta_{\text{I}1}$  is non-zero. We use the following test statistic:

$$t = \frac{\hat{\beta}_1 - 0}{SE(\hat{\beta}_1)}$$

# Hypothesis testing

## 3. Compute the statistics :

Using the estimated  $\beta, SE(\beta)$  we calculate the t-statistic.

## 4. Reject or not reject the hypothesis:

If there is really no relationship between  $X$  and  $Y$ , then we expect that will have a *t-distribution with  $n-2$  degrees of freedom*.

To compute the probability of observing any value equal to  $|t|$  or larger, assuming  $\beta \downarrow 1 = 0$  is easy. We call this probability the p-value.

*a small p-value indicates that it is unlikely to observe such a substantial association between the predictor and the response due to chance*

# Things to Consider

## Comparison of Two Models

How do we choose from two different models?

## Model Fitness

How does the model perform predicting?

## Evaluating Significance of Predictors

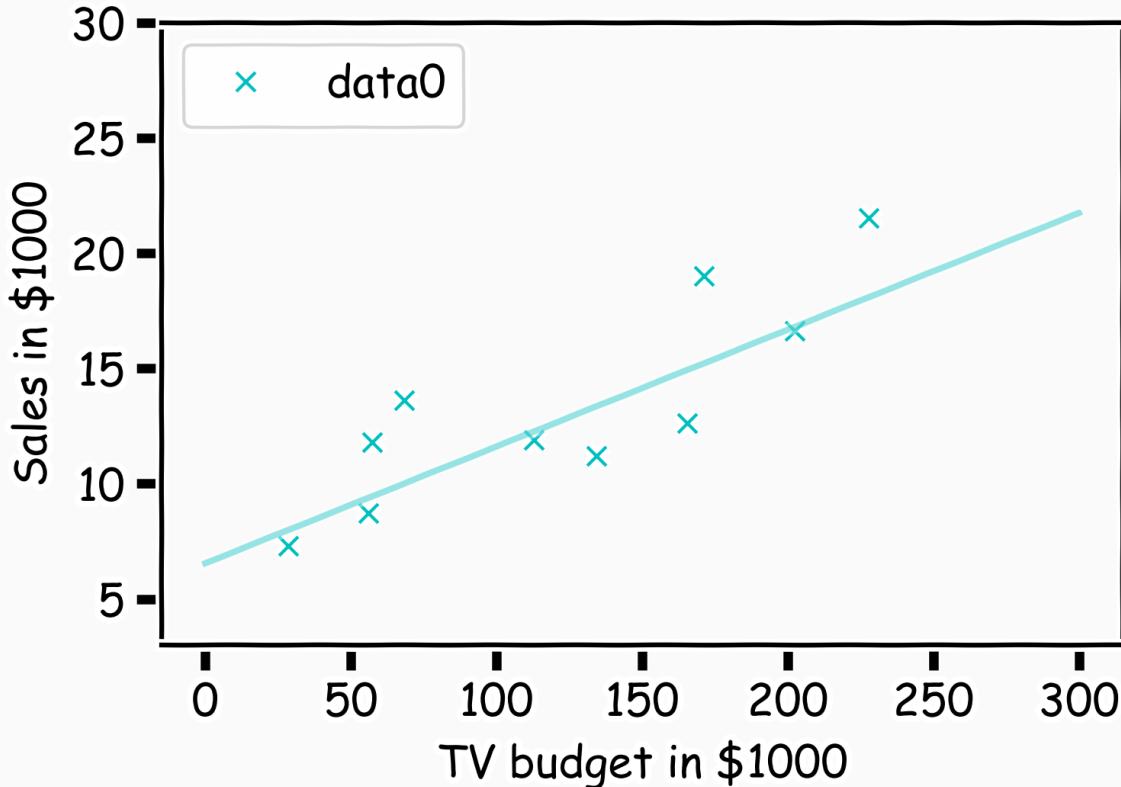

Does the outcome depend on the predictors?

## How well do we know $f$

The confidence intervals of our  $f$

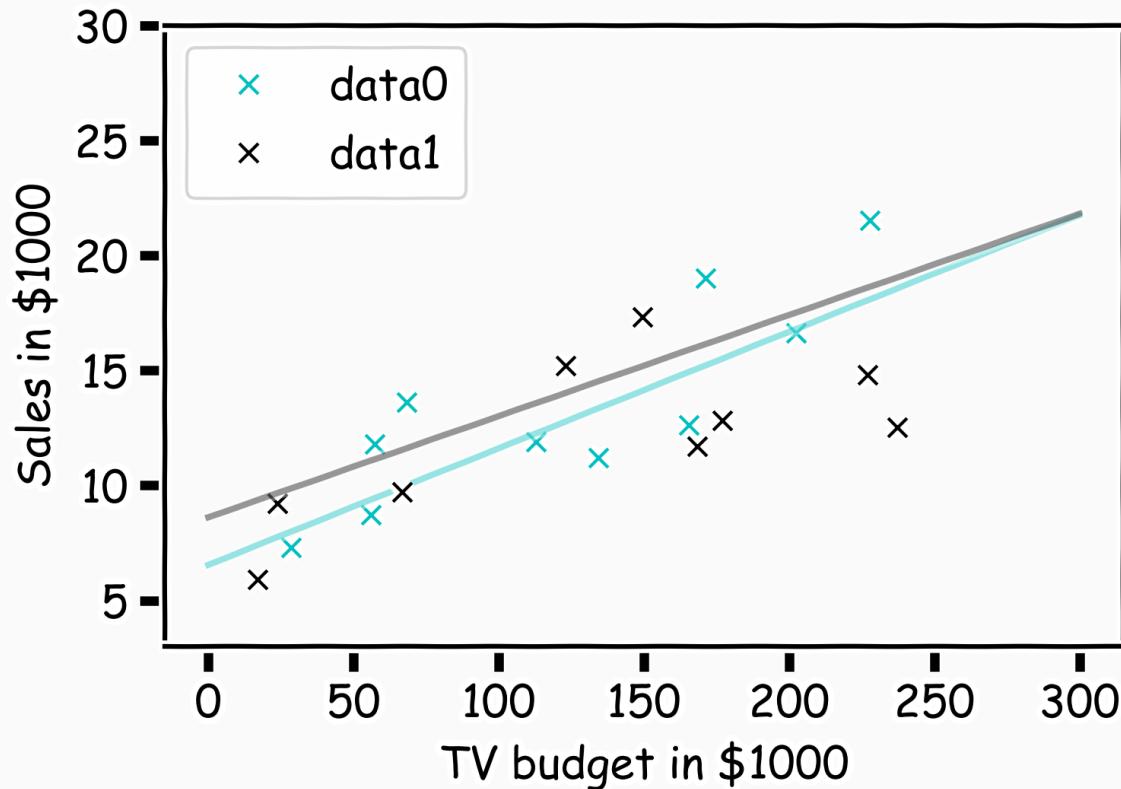

# How well do we know $f$ ?

Our confidence in  $f$  is directly connected with the confidence in  $\beta$ s. So for each  $\beta$  we can determine the model.

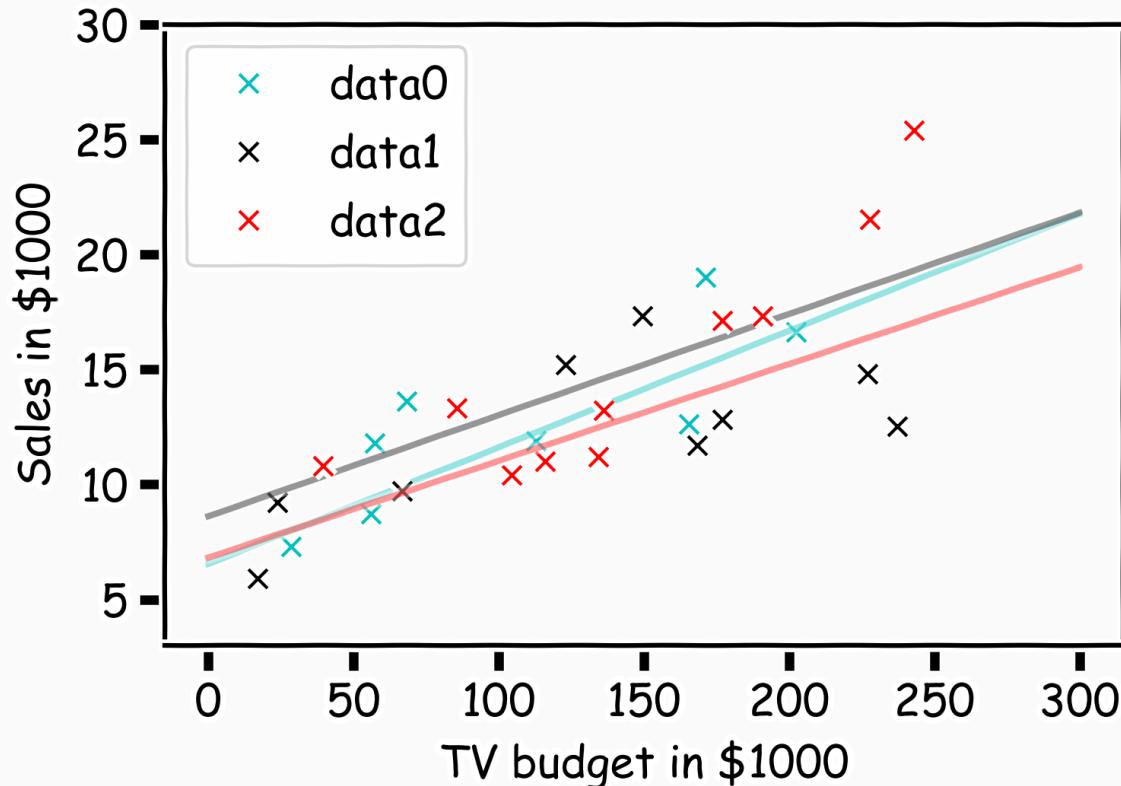

# How well do we know $f$ ?

Here we show two different sets of models given the fitted coefficients for a given subsample

# How well do we know $f$ ?

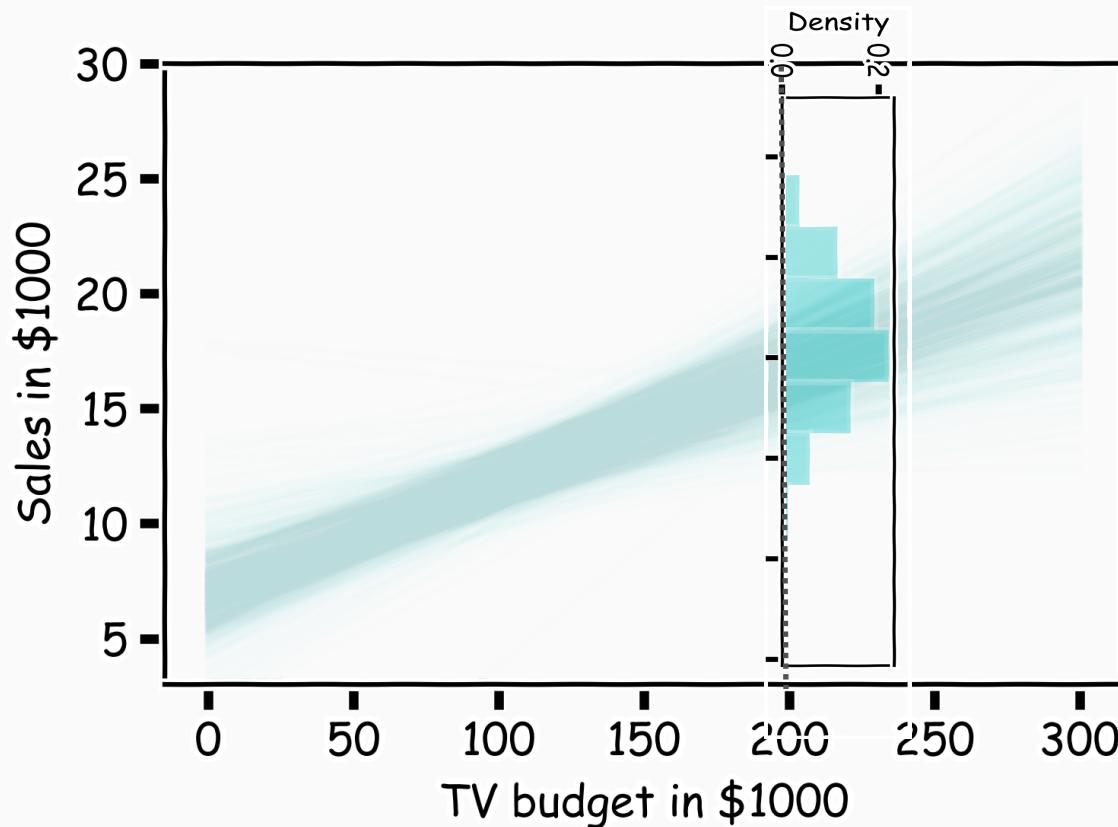

There is one such regression line for every imaginable sub-sample.

# How well do we know $f$ ?

Below we show all regression lines for a thousand of such sub-samples.

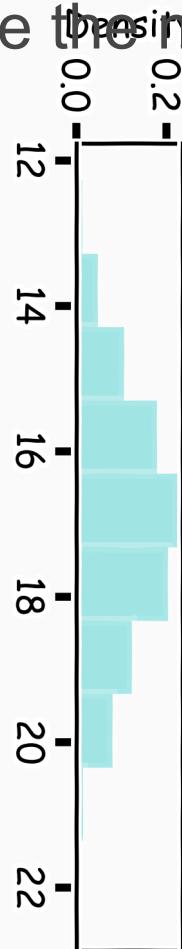

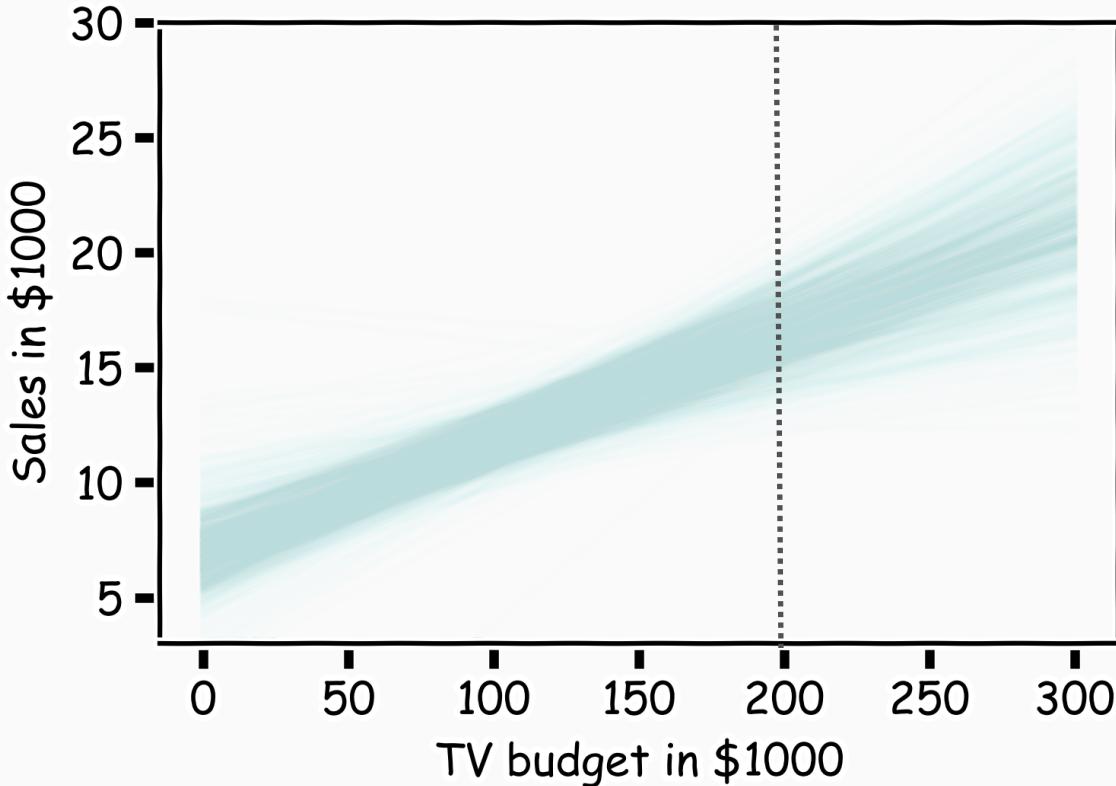

For a given  $x$ , we examine the distribution of  $f$ , and determine the mean and standard deviation.

# How well do we know $f$ ?

Below we show all regression lines for a thousand of such sub-samples.

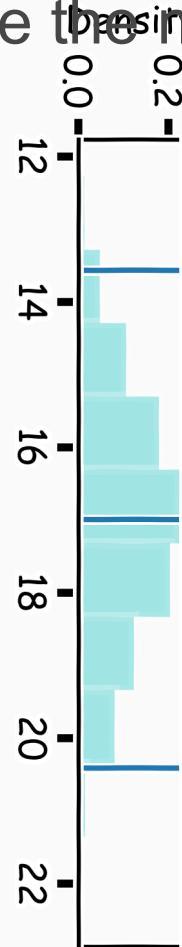

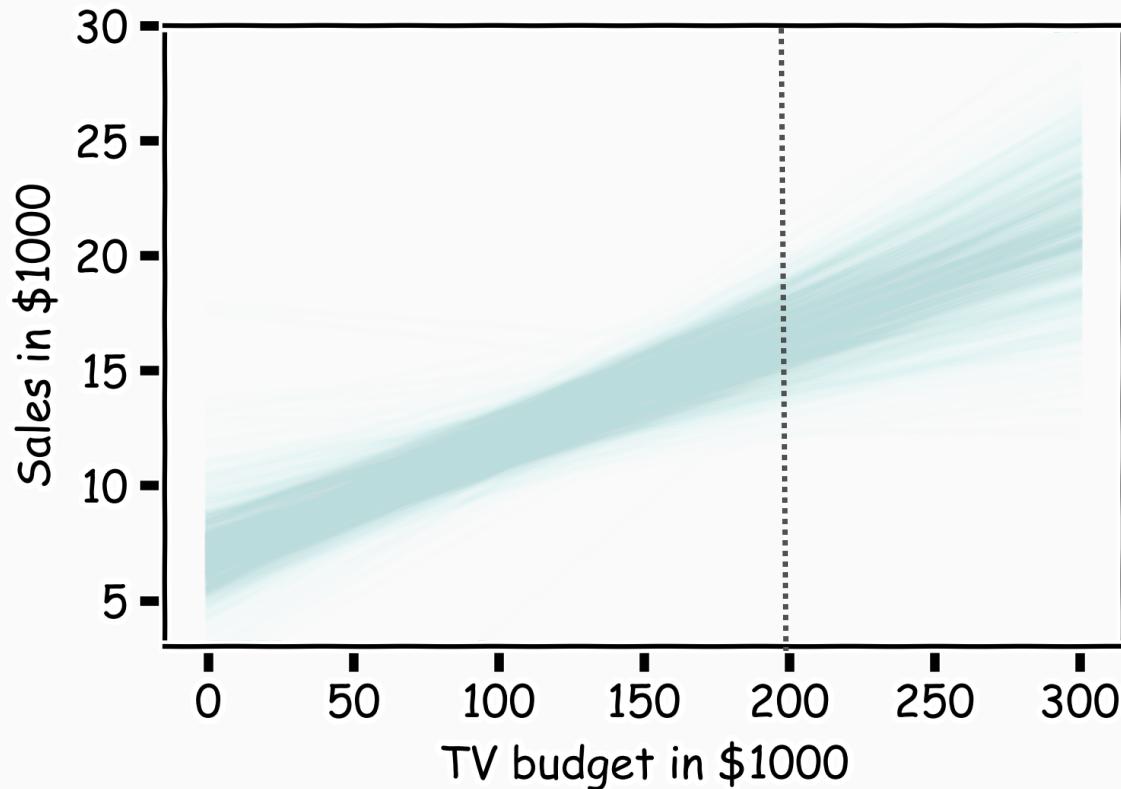

For a given  $x$ , we examine the distribution of  $f$ , and determine the mean and standard deviation.

# How well do we know $f$ ?

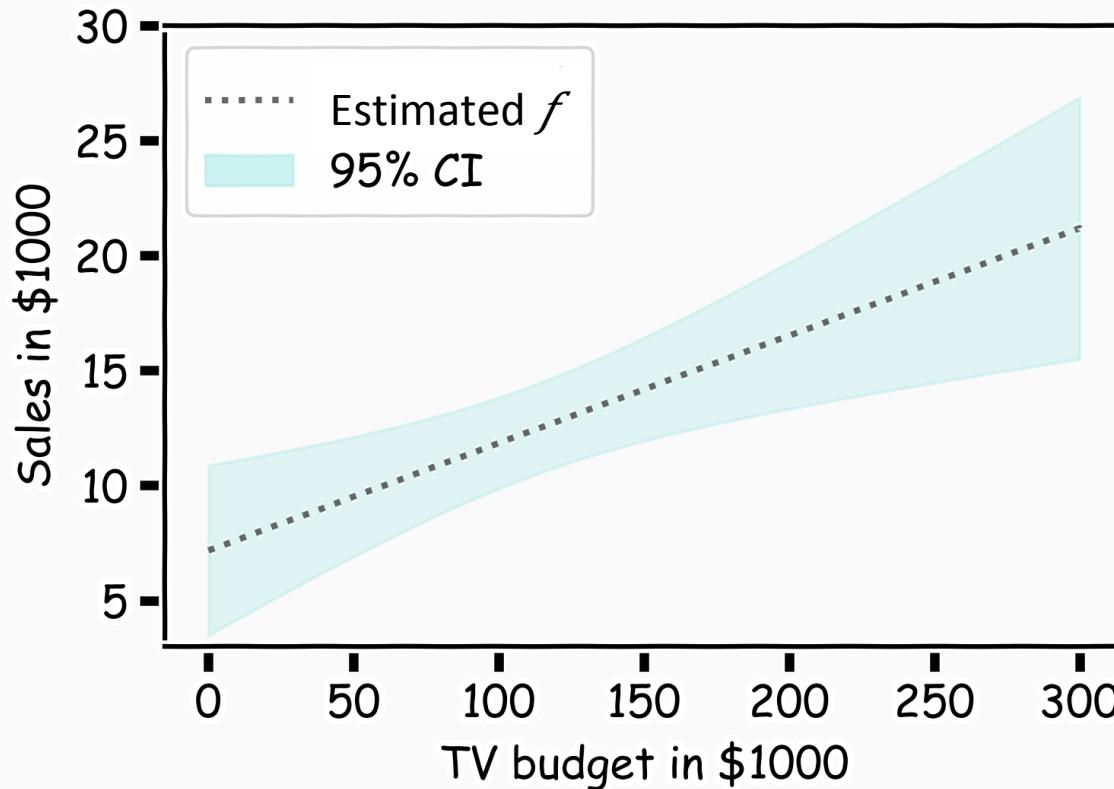

Below we show all regression lines for a thousand of such sub-samples.

For a given  $x$ , we examine the distribution of  $f$ , and determine the mean and standard deviation.

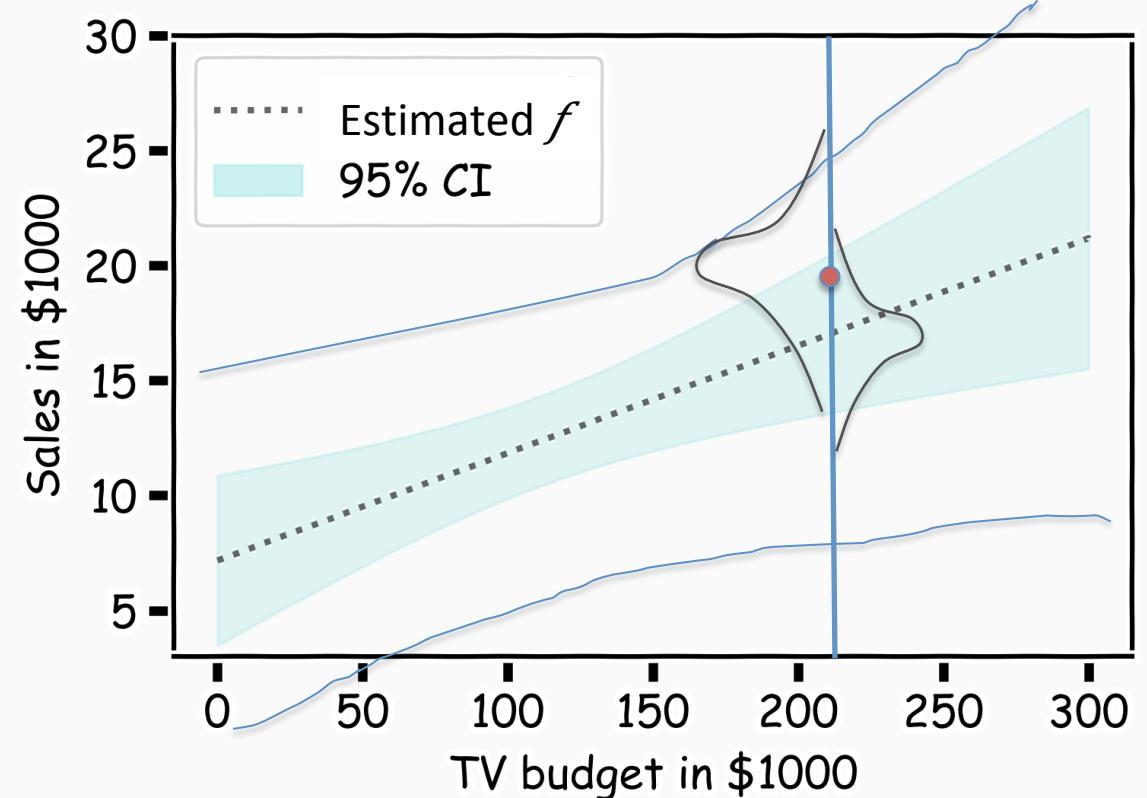

# How well do we know $f$ ?

For every  $x$ , we calculate the mean of the models,  $f$  (shown with dotted line) and the 95% CI of those models (shaded area).

# Confidence in predicting $y$

- For a given  $x$
- We have a distribution of models  $f(x)$
- For each of these  $f(x)$
- The prediction  $y \sim N(f, \sigma \downarrow \epsilon)$
- The prediction CI is then

# Multiple Linear Regression

# Multiple Linear Regression

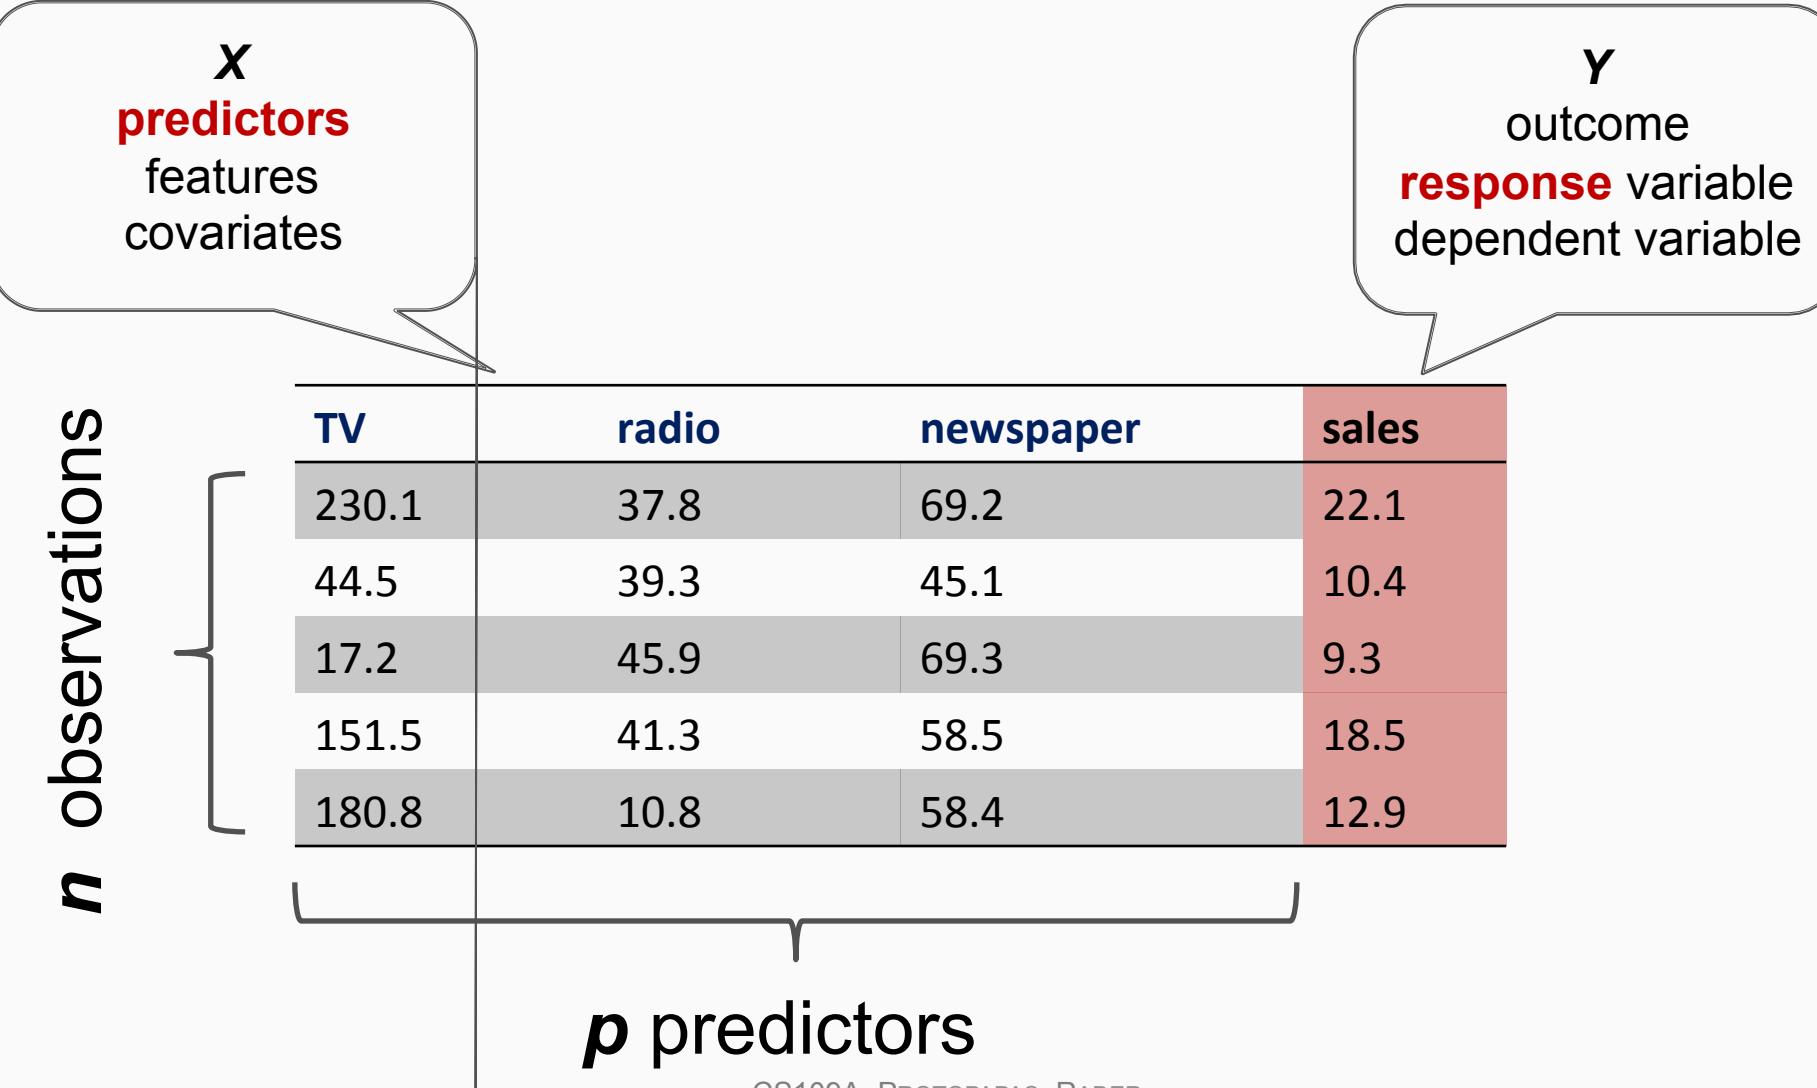

---

If you have to guess someone's height, would you rather be told

- Their weight, only
- Their weight and gender
- Their weight, gender, and income
- Their weight, gender, income, and favorite number

Of course, you'd always want as much data about a person as possible. Even though height and favorite number may not be strongly related, at worst you could just ignore the information on favorite number. We want our models to be able to take in lots of data as they make their predictions.

# Response vs. Predictor Variables

The diagram illustrates a data matrix with observations on the vertical axis and predictors on the horizontal axis. A bracket on the left labeled  $n$  observations spans five rows of data. A bracket at the bottom labeled  $p$  predictors spans four columns of data. A callout bubble labeled **X** predictors features, covariates points to the first three columns. Another callout bubble labeled **Y** outcome, **response** variable, dependent variable points to the last column, which is shaded red.

	TV	radio	newspaper	sales
230.1	37.8	69.2	22.1	
44.5	39.3	45.1	10.4	
17.2	45.9	69.3	9.3	
151.5	41.3	58.5	18.5	
180.8	10.8	58.4	12.9	

# Multilinear Models

In practice, it is unlikely that any response variable  $Y$  depends solely on one predictor  $x$ . Rather, we expect that  $Y$  is a function of multiple predictors  $f(X \downarrow 1, \dots, X \downarrow J)$ . Using the notation we introduced last lecture,

$$Y = y \downarrow 1, \dots, y \downarrow n, \quad X = X \downarrow 1, \dots, X \downarrow J \text{ and } X \downarrow j = x \downarrow 1j, \dots, x \downarrow ij, \dots, x \downarrow nj$$

In this case, we can still assume a simple form for  $f$  - a multilinear form:

$$\hat{Y} = f(X_1, \dots, X_J) + \epsilon = \hat{\beta}_0 + \hat{\beta}_1 X_1 + \hat{\beta}_2 X_2 + \dots + \hat{\beta}_J X_J + \epsilon$$

# Multiple Linear Regression

Again, to fit this model means to compute  $\beta_0, \dots, \beta_J$  or to minimize a loss function; we will again choose the MSE as our loss function.

Given a set of observations,

$$\{(x_{1,1}, \dots, x_{1,J}, y_1), \dots, (x_{n,1}, \dots, x_{n,J}, y_n)\},$$

the data and the model can be expressed in vector notation,

$$\mathbf{Y} = \begin{pmatrix} y_1 \\ \vdots \\ y_y \end{pmatrix}, \quad \mathbf{X} = \begin{pmatrix} 1 & x_{1,1} & \dots & x_{1,J} \\ 1 & x_{2,1} & \dots & x_{2,J} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_{n,1} & \dots & x_{n,J} \end{pmatrix}, \quad \boldsymbol{\beta} = \begin{pmatrix} \beta_0 \\ \beta_1 \\ \vdots \\ \beta_J \end{pmatrix},$$

# Multiple Linear Regression

---

The model takes a simple algebraic form:

$$\mathbf{Y} = \mathbf{X}\beta + \epsilon$$

Thus, the MSE can be expressed in vector notation as

$$\text{MSE}(\beta) = \frac{1}{n} \|\mathbf{Y} - \mathbf{X}\beta\|^2$$

Minimizing the MSE using vector calculus yields,

$$\hat{\beta} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{Y} = \underset{\beta}{\operatorname{argmin}} \text{MSE}(\beta).$$

# Collinearity

---

Collinearity refers to the case in which two or more predictors are correlated (related).

We will re-visit collinearity in the next lectures, but for now we want to examine how does collinearity affects our confidence on the coefficients and consequently on the importance of those coefficients.

First let's look some examples:

# Collinearity

## Three individual models

**TV**

Coef.	Std.Err.	t	P> t	[0.025	0.975]

$\beta \downarrow NE$ <i>WS</i>	0.013	0.028	2.338	0.0203	0.008	0.035

# Collinearity

---

Collinearity refers to the case in which two or more predictors are correlated (related).

We will re-visit collinearity in the next lectures, but for now we want to examine how does collinearity affects our confidence on the coefficients and consequently on the importance of those coefficients.

Assuming uncorrelated noise then we can show:

$$SE(\beta_1) = \sigma^2 (XX^T)^{-1}$$

# Finding Significant Predictors: Hypothesis Testing

For checking the significance of linear regression coefficients:

1. we set up our hypotheses  $H_0$  :

$$H_0 : \beta_0 = \beta_1 = \dots = \beta_J = 0 \quad (\text{Null})$$

$$H_1 : \beta_j \neq 0, \text{ for at least one } j \quad (\text{Alternative})$$

2. we choose the  $F$ -stat to evaluate the null hypothesis,

$$F = \frac{\text{explained variance}}{\text{unexplained variance}}$$

# Finding Significant Predictors: Hypothesis Testing

3. we can compute the  $F$ -stat for linear regression models by

$$F = \frac{(\text{TSS} - \text{RSS})/J}{\text{RSS}/(n - J - 1)}, \quad \text{TSS} = \sum_i (y_i - \bar{y}), \text{RSS} = \sum_i (y_i - \hat{y}_i)$$

4. If  $F=1$  we consider this evidence for  $H_0$ ; if  $F>1$ , we consider this evidence against  $H_0$ .

# Qualitative Predictors

So far, we have assumed that all variables are quantitative. But in practice, often some predictors are **qualitative**.

**Example:** The Credit data set contains information about balance, age, cards, education, income, limit , and rating for a number of potential customers.

Income	Limit	Rating	Cards	Age	Education	Gender	Student	Married	Ethnicity	Balance
14.890	3606	283	2	34	11	Male	No	Yes	Caucasian	333
106.02	6645	483	3	82	15	Female	Yes	Yes	Asian	903
104.59	7075	514	4	71	11	Male	No	No	Asian	580
148.92	9504	681	3	36	11	Female	No	No	Asian	964
55.882	4897	357	2	68	16	Male	No	Yes	Caucasian	331

# Qualitative Predictors

---

If the predictor takes only two values, then we create an **indicator** or **dummy variable** that takes on two possible numerical values.

For example for the gender, we create a new variable:

$$x_i = \begin{cases} 1 & \text{if } i \text{ th person is female} \\ 0 & \text{if } i \text{ th person is male} \end{cases}$$

We then use this variable as a predictor in the regression equation.

$$y_i = \beta_0 + \beta_1 x_i + \epsilon_i = \begin{cases} \beta_0 + \beta_1 + \epsilon_i & \text{if } i \text{ th person is female} \\ \beta_0 + \epsilon_i & \text{if } i \text{ th person is male} \end{cases}$$

# Qualitative Predictors

---

**Question:** What is interpretation of  $\beta_{\cdot 0}$  and  $\beta_{\cdot 1}$  ?

# Qualitative Predictors

---

**Question:** What is interpretation of  $\beta_{\cdot 0}$  and  $\beta_{\cdot 1}$  ?

- $\beta_{\cdot 0}$  is the average credit card balance among males,
- $\beta_{\cdot 0} + \beta_{\cdot 1}$  is the average credit card balance among females,
- and  $\beta_{\cdot 1}$  the average difference in credit card balance between females and males.

**Exercise:** Calculate  $\beta_{\cdot 0}$  and  $\beta_{\cdot 1}$  for the Credit data.

You should find  $\beta_{\cdot 0} \sim \$509, \beta_{\cdot 1} \sim \$19$

# More than two levels: One hot encoding

Often, the qualitative predictor takes more than two values (e.g. ethnicity in the credit data).

In this situation, a single dummy variable cannot represent all possible values.

We create additional dummy variable as:

$$x_{i,1} = \begin{cases} 1 & \text{if } i\text{ th person is Asian} \\ 0 & \text{if } i\text{ th person is not Asian} \end{cases}$$

$$x_{i,2} = \begin{cases} 1 & \text{if } i\text{ th person is Caucasian} \\ 0 & \text{if } i\text{ th person is not Caucasian} \end{cases}$$

# More than two levels: One hot encoding

We then use these variables as predictors, the regression equation becomes:

$$y_i = \beta_0 + \beta_1 x_{i,1} + \beta_2 x_{i,2} + \epsilon_i = \begin{cases} \beta_0 + \beta_1 + \epsilon_i & \text{if } i\text{ th person is Asian} \\ \beta_0 + \beta_2 + \epsilon_i & \text{if } i\text{ th person is Caucasian} \\ \beta_0 + \epsilon_i & \text{if } i\text{ th person is AfricanAmerican} \end{cases}$$

Again the interpretation

# Beyond linearity

---

In the Advertising data, we assumed that the effect on sales of increasing one advertising medium is independent of the amount spent on the other media.

If we assume linear model then the average effect on sales of a one-unit increase in TV is always  $\beta_{TV} \downarrow 1$ , regardless of the amount spent on radio.

**Synergy effect or interaction effect** states that when an increase on the radio budget affects the effectiveness of the TV spending on sales.

# Beyond linearity

---

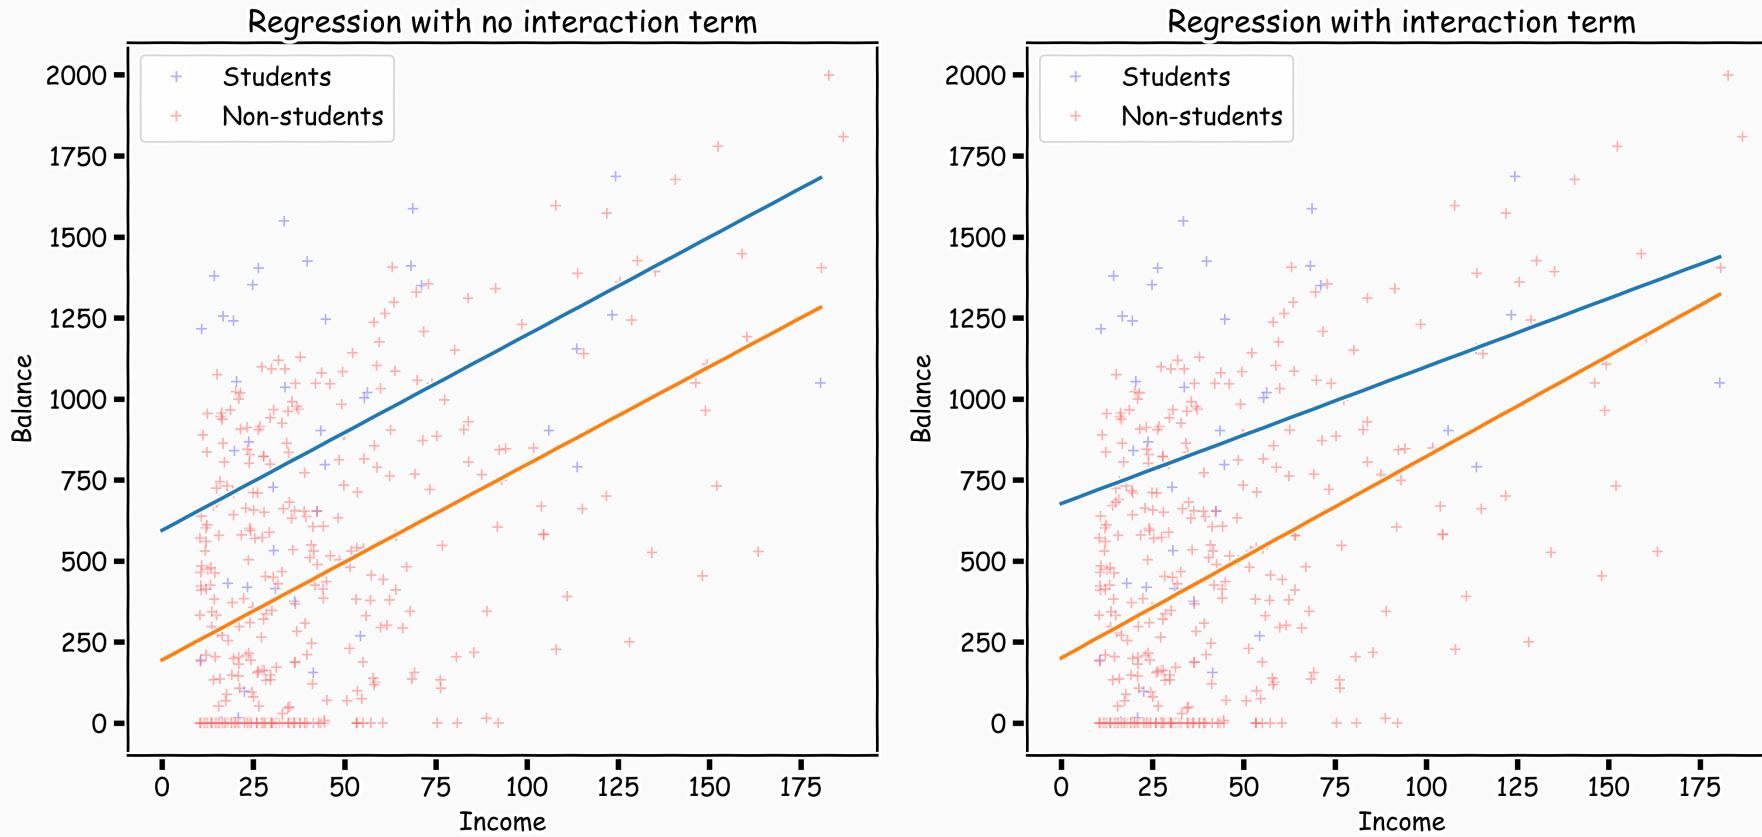

We change

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \epsilon$$

To

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \boxed{\beta_3 X_1 X_2} + \epsilon$$

What does it mean?

# Predictors predictors predictors

---

We have a lot predictors!

Is it a problem?

Yes: Computational Cost

Yes: Overfitting

Wait there is more ...

# Polynomial Regression

# Polynomial Regression

The simplest non-linear model we can consider, for a response  $Y$  and a predictor  $X$ , is a polynomial model of degree  $M$ ,

$$y = \beta_0 + \beta_1 x + \beta_2 x^2 + \dots + \beta_M x^M + \epsilon.$$

Just as in the case of linear regression with cross terms, polynomial regression is a special case of linear regression - we treat each  $x^{1:m}$  as a separate predictor. Thus, we can write

$$\mathbf{Y} = \begin{pmatrix} y_1 \\ \vdots \\ y_n \end{pmatrix}, \quad \mathbf{X} = \begin{pmatrix} 1 & x_1^1 & \dots & x_1^M \\ 1 & x_2^1 & \dots & x_2^M \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_n^1 & \dots & x_n^M \end{pmatrix}, \quad \boldsymbol{\beta} = \begin{pmatrix} \beta_0 \\ \beta_1 \\ \vdots \\ \beta_M \end{pmatrix}.$$

# Polynomial Regression

---

Again, minimizing the MSE using vector calculus yields,

$$\hat{\boldsymbol{\beta}} = \underset{\boldsymbol{\beta}}{\operatorname{argmin}} \text{MSE}(\boldsymbol{\beta}) = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{Y}.$$
